ABSTRACT

SECCO is a survey devoted to the search for stellar counterparts within Ultra Compact High Velocity Clouds that are candidate low mass / low luminosity galaxies. In this contribution we present the results of a set of simulations aimed at the quantitative estimate of the sensitivity of the survey as a function of the total luminosity, size and distance of the stellar systems we are looking for. For all our synthetic galaxies we assumed an exponential surface brightness profile and an old and metal-poor population. The synthetic galaxies are simulated both on the images and on the photometric catalogs, taking into account all the observational effects. In the fields where the available observational material is of the top quality ($\approx 36\%$ of the SECCO fields) we detect synthetic galaxies as $\geq 5\sigma$ over-densities of resolved stars down to $\mu_{V,h} \approx 30.0$ mag/arcsec², for $D \leq 1.5$ Mpc, and down to $\mu_{V,h} \approx 29.5$ mag/arcsec², for $D \leq 2.5$ Mpc. In the field with the worst observational material of the whole survey we detect synthetic galaxies with $\mu_{V,h} \leq 28.8$ mag/arcsec² out to $D \leq 1.0$ Mpc, and those with $\mu_{V,h} \leq 27.5$ mag/arcsec² out to $D \leq 2.5$ Mpc. Dwarf galaxies with $M_V = -10.0$, with sizes in the range spanned by known dwarfs, are detected by visual inspection of the images up to $D=5$ Mpc independently of the image quality. In the best quality images dwarfs are partially resolved into stars up to $D=3.0$ Mpc, and completely unresolved at $D=5$ Mpc. As an independent test of the sensitivity of our images to low surface brightness galaxies we report on the detection of several dwarf spheroidal galaxies probably located in the Virgo cluster with $M_V \lesssim -8.0$ and $\mu_{V,h} \lesssim 26.8$ mag/arcsec². The nature of the previously discovered SECCO 1 stellar system, also likely located in the Virgo cluster, is re-discussed in comparison with these dwarfs. While specific for the SECCO survey, our study may also provide general guidelines for detection of faint stellar systems with 8m class telescopes.

Key words. galaxies: dwarf — galaxies: Local Group — galaxies: stellar content — galaxies: ISM — galaxies: photometry

1. Introduction

Within the standard Λ -Cold Dark Matter (CDM) cosmology it is generally accepted that baryonic physics has a significant impact in shaping the evolution of dwarf galaxies. All the relevant processes (e.g., re-ionization, Supernova feedback, ram-pressure stripping) act by preventing/quenching star formation in low-mass halos ($M \leq 10^9 M_\odot$, mini-halos, after

Ricotti 2009, and references therein). Within this framework, the inclusion of baryonic physics in CDM N-body models of galaxy formation can strongly mitigate the long standing *missing satellites* problem (Kauffmann, White & Guiderdoni 1993; Klypin et al. 1999; Moore et al. 1999; Kravtsov et al. 2004, and references therein). Independently of the actual ability of these models to capture all the complex events leading to galaxy formation, their general prediction is that there should be a significant number of dark matter mini-halos containing $10^5 - 10^7 M_\odot$ of baryons in the form of neutral hydrogen, with or without an associated (small) stellar component (Ricotti 2009; Sawala et al. 2013). The observational detection of these dark and *almost-dark* galaxies is a crucial frontier for the validation of the current cosmological paradigm on the small-scales (see, e.g., Cannon et al. 2015).

[★] Based on data acquired using the Large Binocular Telescope (LBT). The LBT is an international collaboration among institutions in the United States, Italy, and Germany. LBT Corporation partners are The University of Arizona on behalf of the Arizona university system; Istituto Nazionale di Astrofisica, Italy; LBT Beteiligungsgesellschaft, Germany, representing the Max-Planck Society, the Astrophysical Institute Potsdam, and Heidelberg University; The Ohio State University; and The Research Corporation, on behalf of The University of Notre Dame, University of Minnesota and University of Virginia.

While modern all-sky surveys allowed us to unveil a large number of very faint gas-deficient galaxies around the Milky Way (the so called Ultra Faint Dwarfs - UFD Belokurov 2013) the hypothesised gas-rich and star-poor dwarfs are still to be found. All UFDs were found as stellar over-densities; only one of them was subsequently found to have a neutral hydrogen component and ongoing star formation, Leo T (Irwin et al. 2007). On the other hand the recent identification of the faint star-forming dwarf galaxy Leo P (Giovannelli et al. 2013) opened a new path for the discovery of these systems. In fact, Leo P was discovered as the stellar counterpart of an Ultra Compact High Velocity Cloud (UCHVC) previously identified by the ALFALFA HI survey (Giovannelli et al. 2007). Along this line, Adams et al. (2013, A13 hereafter) selected from the ALFALFA database a sample of 59 UCHVCs lacking any visible counterpart in SDSS images, that they proposed as good candidates to be associated with mini-halos in the distance range $0.25 \text{ Mpc} \leq D \leq 2.0 \text{ Mpc}$. Similarly, Saul et al. (2013, S12 hereafter), identified 27 UCHVCs from their GALFA-HI survey as local “galaxy candidates” (see Sand et al. 2015, for a critical comparison of the two sources of candidates). The only way to directly confirm these candidates as genuine dwarf galaxies would be to identify a concomitant stellar counterpart whose distance could be estimated, as done in the case of Leo P (McQuinn et al. 2013).

The search for stellar counterparts in these UCHVCs is the main scientific goal of the SECCO (*searching for StEllar Counterparts of COmpact high velocity clouds*) survey¹, that we presented, together with the results from its first phase, in Bellazzini et al. (2015a, Pap I hereafter). In particular we used the LBC cameras (Giallongo et al. 2008), mounted at the Large Binocular Telescope² (Mt Graham, AZ) to obtain deep homogeneous wide-field imaging and photometry in two broad bands (g, r) of 25 UCHVCs carefully selected from the A13 sample, plus Leo P, taken as a template. In Pap I we concluded that no obvious stellar counterpart in the range of distances indicated by A13 can be associated to the surveyed UCHVCs. On the other hand we identified two candidates that are expected to lie at larger distance. The follow-up of one of them revealed that it is indeed a very faint and dark star-forming galaxy likely belonging to the Virgo cluster of galaxies (SECCO 1, Bellazzini et al. 2015b); this result was independently confirmed by Sand et al. (2015).

Several teams worldwide are performing similar surveys (see, e.g. Tollerud et al. 2015; Sand et al. 2015; Donovan Meyer et al. 2015). In this context SECCO is the first project (and, the only one, so far) to have performed a systematic homogeneous search, since all the targets have been observed with the same set up, albeit not always with the same observing conditions (see Pap I for details and discussion). It is also based on the deepest images; our photometry typically reaches $r \simeq 26.5$. Finally SECCO has been built to allow a quantitative estimate of the significance of non-detections. In Pap I we presented a first limited set of simulations with synthetic galaxies, taking into account all the observational effects, that lead us to conclude that we cannot have missed any dwarf having integrated absolute magnitude $M_V \leq -8.0$ and half-light radii $R_h \leq 300 \text{ pc}$ lying within 1.5 Mpc from us. In the present contribution we extend our set of experiments with synthetic galaxies in order to explore the sensitivity limits of our survey in terms of total luminosity, size and distance of the stellar systems we are looking for. The full range of observational conditions encountered in SECCO is also probed.

Fig. 1. Integrated absolute V magnitude versus the logarithm of the half light radius for dwarf galaxies in the most recent version of the M12 catalog (filled circles). The mean M_V vs. $\log R_h$ relation by Brasseur et al. (2011) is plotted as a continuous line; the curves bracketing $\pm 1\sigma$ and $\pm 2\sigma$ range about that relation are plotted as dashed and dotted lines respectively. The central not-shaded area of the figure highlights the range of M_V considered in the present study. Large empty circles are the synthetic dwarf galaxies studied in this paper (see also Fig. 2).

This is an essential complement to SECCO observations, providing the final complete result of our screening, at least for the local volume. Moreover, the results of our experiments, performed both on star counts and directly on images, provide a useful set of cases that can be used as a guideline for interpreting the results from similar surveys and to plan new ones.

The paper is organised as follows: in Sect. 2 we describe the synthetic galaxies we adopt in our study. Sect. 3 explores the sensitivity of the search for stellar over-densities by means of density maps performed in Pap I. In Sect. 4 we show and discuss our main results on the sensitivity of the visual inspection of images, also performed in Pap I. In Sect. 5 we report on the discovery of seven Low Surface Brightness dwarfs likely belonging to the Virgo cluster of galaxy and we use these detection to get an independent validation of the sensitivity of our search by visual inspection. Finally, in Sect. 6 we summarise the main conclusion of our analysis, also briefly re-discussing the results of Pap-I at the light of the present study. A long table summarising the results of the analysis on density maps is provided in Appendix A, while the images of synthetic galaxies are collected in Appendix B.

2. Synthetic galaxies

The synthetic galaxies that we inject into our photometric catalogs (to test the sensitivity of the detection of over-densities in stellar density maps) or in our stacked images (to test the sensitivity of the detection by visual inspection) have the same properties as those adopted and described in Pap I. Here we summarise their main features for the reader’s convenience and we

-7.0	489	30.0
-6.0	141	28.3
-6.0	245	29.5
-6.0	426	30.7
-5.0	123	29.0
-5.0	213	30.2
-5.0	371	31.4

Notes. All the synthetic galaxies have exponential surface density profiles. M_V is the integrated absolute magnitude in V band. $\mu_{V,h}$ is the average surface brightness within R_h .

illustrate the space of parameters that is explored in the present analysis.

The galaxies consist of a synthetic stellar population of old and metal-poor stars, obtained from the Bressan et al. (2012) models. The mass of the stars are extracted (down to the hydrogen burning limit) from a mass function $N(m) \propto m^{-x}$, with $x = -2.35$ for $m > 0.5 M_\odot$ and $x = -1.30$ for $m \leq 0.5 M_\odot$. The stars span a small range in metallicity ($\sigma_{[Fe/H]} = 0.1$ dex)

with mean metallicity $[Fe/H] = -1.8$ (see Pap I). Star formation starts 13.0 Gyr ago and declines exponentially with time with an exponential scale of 0.5 Gyr. The population is intended to be a fair representation of very faint dwarfs ($M_V \geq -10.0$) that are known to be dominated by old and metal-poor populations (see, e.g., Mateo 1998; McConnachie 2012; Weisz et al. 2014). The choice of a mainly old population is conservative, since the lack of bright blue stars makes its detection more difficult than for a star-forming galaxy. On the other hand the inclusion of a young stellar component in our synthetic galaxies would have implied a strong dependency on further assumptions, e.g. on star formation efficiency and initial mass function.

The synthetic stars are spatially distributed in the plane of the sky according to an exponential profile³. This is known to be an appropriate choice for a wide range of low-luminosity dwarfs (Mateo 1998; Martin, de Jong & Rix 2008) and it is very simple, being specified only by the value of its half-light radius R_h and a luminosity normalisation (here the integrated magnitude, M_V , that is fixed by extracting a fraction of the synthetic stellar population that sums up the required total luminosity). Circular (spherical) symmetry is always adopted.

We consider only dwarf galaxies fainter than $M_V = -10.0$. The performed experiments reveal that this choice is adequate, since galaxies with $M_V \leq -10.0$ are detected in SECCO over the whole range of parameters relevant for our purposes, independently of the quality of the observational material (see Sect. 4, below). On the other hand, our results suggest that dwarfs fainter than $M_V = -5.0$ would be detected only if they are more compact than average and have $D \lesssim 0.5$ Mpc. The half-light radius of dwarf galaxies is known to scale with their absolute integrated magnitude (see, e.g., Tolstoy, Hill & Tosi et al. 2009; McConnachie 2012, and references therein). While this relation is likely significantly shaped by incompleteness, especially on the low surface brightness side and for $M_V \gtrsim -6.0$ (Brasseur et al. 2011), it provides us with a basic guideline for the main goal of the present study, that is to explore the sensitivity of SECCO in the range of *known dwarf galaxies*. In Sect. 3 and Sect. 6 we will show that the adopted approach allow us also to probe the sensitivity of the survey also in regions of the parameter space that are still poorly explored by existing panoramic surveys, in particular for $\mu_{V,h} > 26.0$ mag/arcsec² at $D \gtrsim 1.0$ Mpc.

Brasseur et al. (2011) studied this relation in detail and provided a simple model for the mean half-light radius \bar{R}_h as a function of M_V based on Milky Way and M31 satellites, with well measured standard deviations $\sigma_{\log R_h}$ about the mean relation, taking into account the effect of incompleteness

$$\log(\bar{R}_h(M_V)) = 2.39 + 0.24(M_V + 6.0) \quad \text{with } \sigma_{\log R_h} = 0.06 \quad (1)$$

(see Brasseur et al. 2011, for details). Here, for each value of M_V , we consider synthetic galaxies having $\log(R_h) = \log(\bar{R}_h(M_V))$, $\bar{R}_h(M_V) - 1\sigma_{\log R_h}$, and $\bar{R}_h(M_V) + 1\sigma_{\log R_h}$, to explore the range of sizes spanned by known dwarfs. In the following we will often refer to models with $R_h = \bar{R}_h(M_V)$, $\bar{R}_h(M_V) - 1\sigma_{\log R_h}$, and $\bar{R}_h(M_V) + 1\sigma_{\log R_h}$ as *average*, *compact*, and *diffuse* models, respectively.

In Fig. 1 the Brasseur et al. (2011) model (together with its $\pm 1\sigma_{\log R_h}$ and $\pm 2\sigma_{\log R_h}$ envelopes) is compared to the dwarfs in the Local Volume (LV) from the compilation by McConnachie (2012). Note that, in the range of M_V considered here, systems with $R_h \geq \bar{R}_h(M_V) + 1\sigma_{\log R_h}$ are very rare, while several dwarfs

³ Here we adopt the formalism introduced by Ciotti & Bertin (1999) for Sersic models, with $R_h = R_e$. The exponential profile is the case $m = 1$.

have $R_h \leq \bar{R}_h(M_V) - 1\sigma_{\log R_h}$. This may be partly due to selection effects; however the asymmetry remains also for $M_V \leq -8.0$, suggesting that dwarfs more compact than average are more frequent than dwarfs more extended than average.

The grid of M_V , R_h and $\mu_{V,h}$ ⁴ of the synthetic galaxies considered here is reported in Table 1 and illustrated in Fig. 1 and Fig. 2. Knots of the grid have been actually explored only if required. For example, if for a given M_V the dwarfs with $R_h = \bar{R}_h(M_V)$ are not detected in a given dataset, the exploration of the corresponding $\bar{R}_h(M_V) + 1\sigma_{\log R_h}$ case is pointless, since the detection of more diffuse systems is more difficult.

We adopted a different grid of distances for the density maps and visual inspection experiments. The first ones are sensitive only to galaxies that are at least partially resolved into stars, hence relatively nearby, but can reveal also very faint and diffuse systems. For this set of experiments we simulate the synthetic dwarfs at the distance of 0.25, 0.5, 1.0, 1.5, 2.0, and 2.5 Mpc. On the other hand, the visual inspection can reveal also more distant and unresolved systems. In this case we consider the cases $D = 0.5, 1.0, 2.0, 3.0$, and 5.0 Mpc. A general conclusion from all our experiments with images of synthetic galaxies is that, in agreement with the rule-of-thumb statement made in Pap I, *the distance limit at which we partially resolve dwarfs into stars also in the best observational conditions is $D \simeq 3.0$ Mpc* (see below).

Finally we performed our experiment using (a) a dataset that is representative of the 36 per cent of the SECCO fields observed under the *best observing conditions* (Field B), and (b) the dataset of the field observed under the *worst observing conditions* of the whole survey (Field I, see Pap I). This is intended to bracket the whole range of observing conditions encountered in SECCO and to fully assess the impact of the data quality on the sensitivity of the survey. For reference, we remind that the images of Field B(I) have been obtained with typical seeing of $0.9''(1.4'')$, with a limiting magnitude of the final photometry (as traced by the r_{90} parameter, see Pap I) of $r_{90} = 26.37(r_{90} = 25.59)$. In the following we will often refer to these two cases as to *Best* and *Worst* cases, respectively, for brevity and simplicity.

2.1. Injecting synthetic galaxies into photometric catalogs

The process is described in detail in Pap I. To summarise we use the extensive sets of artificial stars experiments presented in Pap I to transform the catalog of synthetic stars for a given M_V according to all the effects associated to the observation and data reduction, i.e. incompleteness, photometric errors, selection effects.

The synthetic catalog produced in this way is then merged to the original photometric catalog of the fields B and I of the SECCO survey and the surface density maps are derived exactly in the same way as in Pap I. Then we annotate if the synthetic dwarf is detected at $\geq 5\sigma$ or at $\geq 10\sigma$ above the background or not detected. We also verify if the nature of detected over-densities can be firmly established by the inspection of the Color Magnitude Diagram (CMD) within a given radius (taken as R_h , for convenience), compared to the CMD of the surrounding field. This classification process will be illustrated in detail in Sect. 3.

⁴ Average surface brightness within R_h of the corresponding exponential model, derived as $\mu_{V,h} = M_V + 5\log R_h + 23.567$, where R_h is expressed in parsecs.

2.2. Injecting synthetic galaxies into stacked images

The magnitudes and positions of the stars in the synthetic catalogues described in the previous sections are used to inject the synthetic galaxies in the real images with the DAOPHOT/ADDSTAR routine (Stetson 1987). In short, the routine adds simulated stars into the real images in accordance with their positions and magnitudes, using the Point Spread Function (PSF) model characteristic of each image and used for the photometric reduction (see Pap I).

We have a total of 4 science frames for each field, namely 2 *g* and 2 *r* band exposures. The simulated stars are first added to the best seeing exposure taken as the reference frame. The center of the synthetic object (X_0, Y_0) is placed roughly at the center of the reference frame and far from saturated stars in order to avoid contamination from scattered light⁵. The physical position of each star in the image is simply calculated as $X_s = X_0 + X_c$ and $Y_s = Y_0 + Y_c$, where X_s and Y_s are the coordinates with respect to the coordinates in pixel of the center X_c, Y_c .

The 4 images with the synthetic stars were then fed to MONTAGE2 (Stetson 1987) in order to build a stacked image for each simulation. The latter are used to assess the sensitivity of the SECCO survey through the visual inspections (see Sect. 4).

3. Sensitivity of the density maps

To illustrate the process of detection of synthetic galaxies with density maps we consider the case of a $M_V = -8.0$ dwarf galaxy. In the upper panel of Fig. 3 we show the maps obtained for a $R_h = \bar{R}_h(M_V)$ model observed in the best conditions, and located at the six distance values adopted for this kind of experiments (see Sect. 2.1). It is readily evident that at all the considered distances the synthetic galaxy is detected as an over-density at $\geq 10\sigma$ over the background. While the angular scale varies significantly with the distance, as obvious, there is no doubt that such a stellar system would have been detected in SECCO.

It may be interesting to note that in the $D=0.25$ Mpc case the over-density exceeds the limits of the studied field⁶, still it emerges clearly above the background. The inspection of the corresponding CMD in the lower panel of Fig. 3 clearly reveals the presence of an unexpected stellar population, thus confirming the detection beyond any doubt. In the CMDs shown in Fig. 3 and in analogous figures below, we have plotted stars of the synthetic galaxies and of the fore/background population with different colours (grey and black, respectively) for the reader convenience. The distribution of black points provide a view of the typical CMD of the fore/background population in an adjacent

⁵ Note that heavily saturated stars would prevent the detection of a background dwarf if the size of the circle dominated by their light on the image is comparable to the size of the dwarf. The synthetic galaxies considered here typically have $r_h \gtrsim 10''$ (up to $> 60''$). Identifying bright stars in our images we found that stars with $r \lesssim 12.0$ are required to significantly reduce the sensitivity over a circle with radius $\gtrsim 15''$; stars with $r \lesssim 13.0$ obliterate circles with radius $\gtrsim 10''$, those with $r \lesssim 15.0$ obliterate circles with radius $\gtrsim 5''$. These bright stars are rare in our high latitude fields (19 of 25 having galactic latitude $> 50^\circ$). Using the TRILEGAL galactic model (Girardi et al. 2005) we find that the density of $r \lesssim 13.0$ stars in a field with $(l,b)=(90^\circ, 45^\circ)$ is ≈ 1 per 40 arcmin². Hence the impact of chance superposition between a dwarf galaxy and such bright stars should not have a serious impact on our estimate of the sensitivity.

⁶ That, we recall, is the $17.3' \times 7.7'$ field covered by the central LBC chip of each SECCO field.

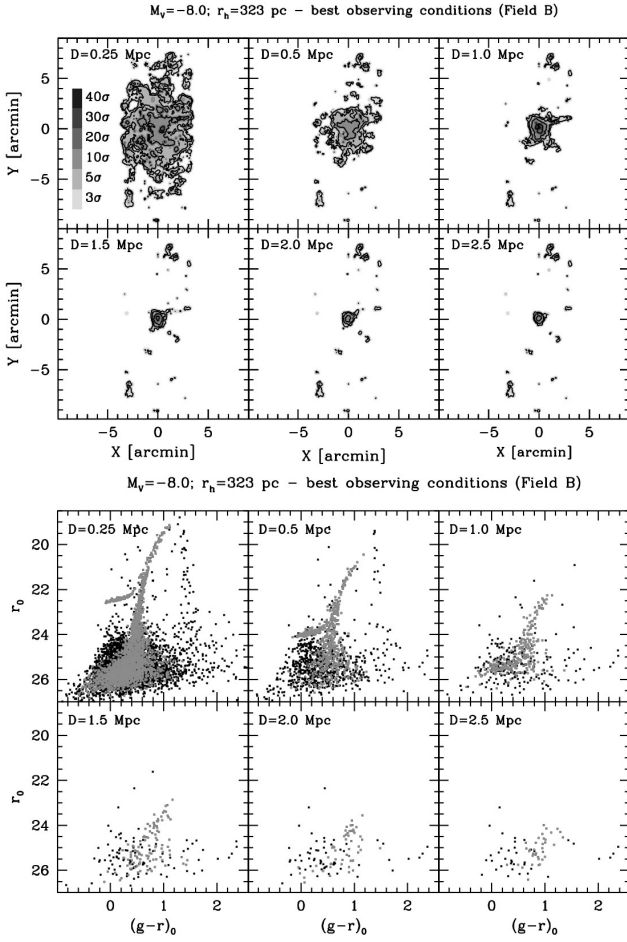

Fig. 3. Upper panel: density maps from a $M_V = -8.0$ synthetic galaxy with $R_h = \bar{R}_h(M_V)$ observed in SECCO (Best case). The galaxy is located at six different distances from $D=0.5$ Mpc to $D=2.5$ Mpc. The density scale is in term of σ over the background (see Pap I). Lower panel: CMD of stars within $1 R_h$ of the center of the synthetic galaxies shown above. Stars from the synthetic population are plotted in grey while field stars are plotted in black.

“blank” field of the same area as those shown in the various panels.

The CMD would allow to unambiguously classify the detected over-densities as local dwarf galaxies (instead of, e.g., clusters/groups of unresolved galaxies, see Pap I) up to $D=1.0$ Mpc. In most cases this would also imply that a reliable distance estimate would have been possible with the SECCO observational material, with accuracy depending on the distance, on the total luminosity and on the stellar population of the considered galaxy. In the $D=1.5$ Mpc case, the CMD does not allow an unambiguous classification and a reliable distance estimate. However it clearly provide support to the detection, strongly suggesting a follow-up of the candidate. On the other hand, the nature of the clean and compact over-densities detected at $D=2.0$ Mpc and $D=2.5$ Mpc cannot be established using the CMD, that is too poorly populated and widened by the large photometric errors near the limiting magnitude of the photometry.

Fig. 4 and Fig. 5 shows the same plots as Fig. 3 but for models with $R_h = \bar{R}_h(M_V) - 1\sigma_{\log R_h}$ and with $R_h = \bar{R}_h(M_V) + 1\sigma_{\log R_h}$, respectively. The comparison of the maps of the compact, average and diffuse models illustrates the strong impact of the galaxy

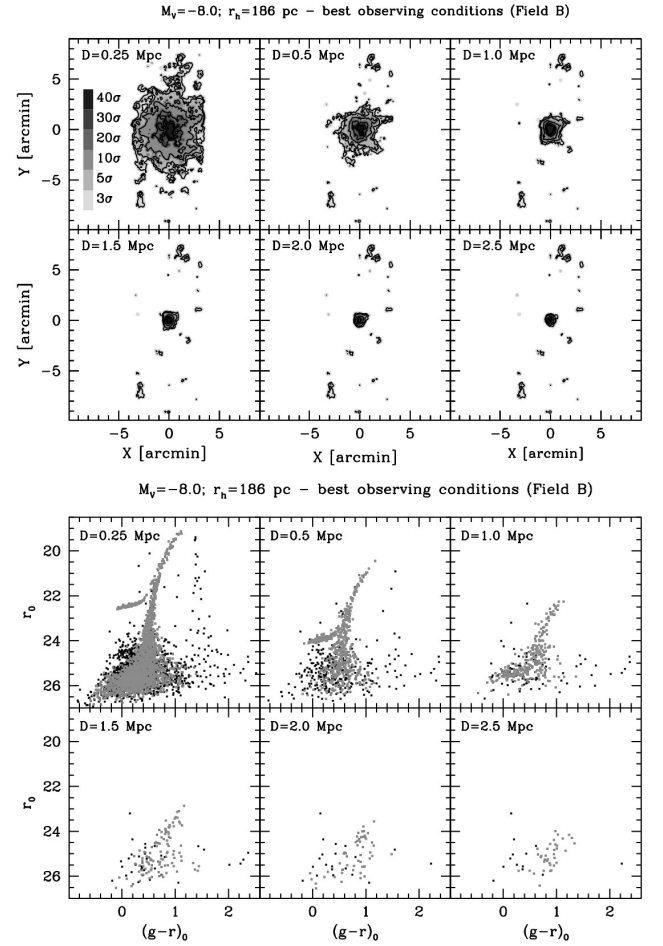

Fig. 4. The same as Fig. 3 for a $M_V = -8.0$ synthetic galaxy with $R_h = \bar{R}_h(M_V) - 1\sigma_{\log R_h}$.

size on the sensitivity of density maps. As expected, compact galaxies are much more clearly and easily detected. The $\geq 10\sigma$ over-densities of the $R_h = \bar{R}_h(M_V)$ case become $\geq 40\sigma$ for the compact model, and in some case reach just $\geq 5\sigma$ for the diffuse model. By definition, the stars from the synthetic galaxies within $1 R_h$ are the same (for each assumed distance) in all the CMDs for the $M_V = -8.0$ galaxy; what changes in the three cases is the actual extension of R_h , leading to the inclusion of more and more field stars in the $R \leq R_h$ CMD⁷. However, in *all the considered cases* the detections for $D \leq 1.5$ Mpc are clearly confirmed, or strongly supported (for $D=1.5$ Mpc), by the inspection of the CMD.

Fig. 6 is the strict analogous of Fig. 3 but for the case of worst quality observational material in SECCO. It can be readily appreciated that, in this case, a $\geq 5\sigma$ over-density is found only for $D \leq 1.5$ Mpc, while more distant galaxies would not be detected. However, in spite of the relatively weak over-density signal, the CMD would provide fairly clear confirmations up to $D \leq 1.0$ Mpc and, possibly, also to $D \leq 1.5$ Mpc.

⁷ We verified that in our models the angular half-light radius is a good approximation of the radius enclosing the 3σ iso-density contour, for detected over-densities. Hence, the adoption of $R \leq R_h$ for the CMDs shown here is just a convenient, simple and uniform choice that should not seriously bias our ability of confirming/detecting a galaxy from its CMD. Please note that in Pap I we checked the CMDs over a wide range of radii for *all the* $\geq 5\sigma$ over-densities detected in our density maps.

Fig. 5. The same as Fig. 3 for a $M_V = -8.0$ synthetic galaxy with $R_h = \bar{R}_h(M_V) + 1\sigma_{\log R_h}$.

Finally, Fig. 7 shows that, in the worst observing conditions, a $M_V = -8.0$ dwarf with $R_h = \bar{R}_h(M_V) + 1\sigma_{\log R_h}$ would never be detected as an over-density in SECCO. It is worth noting that in some case their presence could be revealed by the inspection of the overall CMD of the associated field (in particular for $D \leq 0.5$ Mpc; see, e.g., Fig. 6, lower panel, $D=0.25$ Mpc case). However, to avoid ambiguity in our definition of sensitivity, in the present study we consider only significant ($\geq 5\sigma$) overdensities as valid detections, and use the CMDs only to support the classification of detected objects as genuine dwarfs.

The analysis described above for the $M_V = -8.0$ case has been repeated for all the relevant knots of the grid in Table 1.

A graphical representation of the main results of this analysis is shown in Fig. 8 and Fig. 9. For any considered case and any adopted distance, we classify the synthetic galaxy and symbolise them in the figures according to the following criteria:

1. it is detected as an over-density at $\geq 10\sigma$ (dark grey solid square)
2. it is detected as an over-density at $\geq 5\sigma$ but $< 10\sigma$ (light grey solid square)
3. it is not detected at all (not represented)

Moreover we over-plot a black open square on top of the symbols which represent the cases in which the classification as dwarf galaxy is significantly supported by their CMD. The results of this analysis are shown in Fig. 8 and Fig. 9 for Best and Worst case observations, respectively, and are summarised

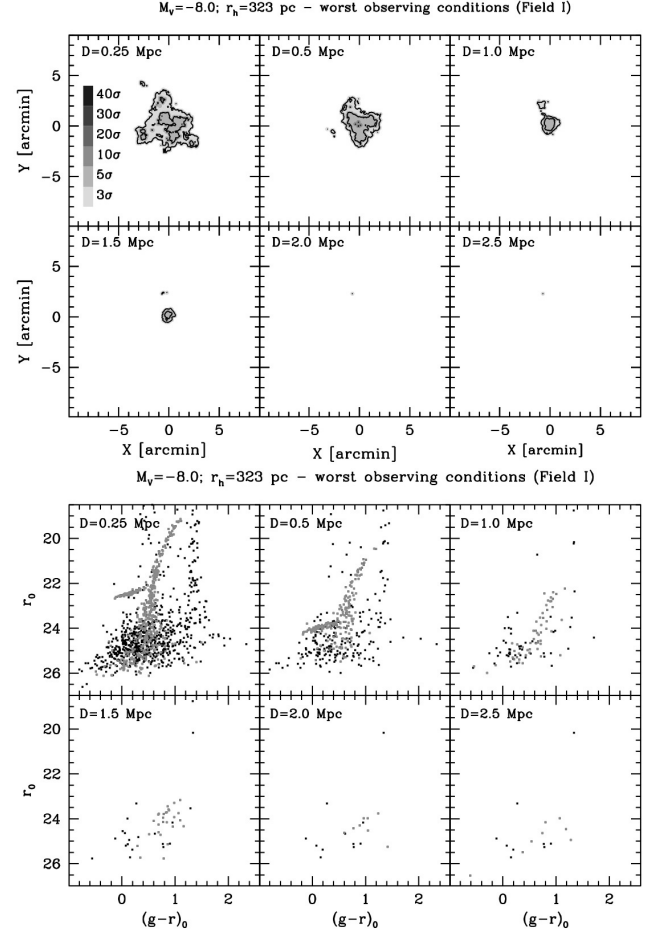

Fig. 6. The same as Fig. 3 ($R_h = \bar{R}_h(M_V)$ models) but for observations in SECCO (Worst case).

Fig. 7. Density maps for the same case as Fig. 6 but for a diffuse model.

in tabular form in Tab. A.1. Fig. 8 shows that any galaxy with $M_V \leq -8.0$ and $D \leq 2.5$ Mpc would have been detected by SECCO observations independently of its actual size, in the $\bar{R}_h(M_V) \pm 1\sigma_{\log R_h}$ range considered here, if it falls within one of the best-quality SECCO fields, similar to the Best case considered here. In this case, galaxies with $M_V \leq -7.0$ are detected out to $D = 2.0$ Mpc, if they have $R_h \leq \bar{R}_h(M_V)$, and out to $D = 1.5$ Mpc if they are diffuse. In case of compact galax-

Fig. 8. Summary of the density map sensitivity experiments for *Best case* SECCO observations. Light-grey squares indicate $\geq 5\sigma$ but $< 10\sigma$ over-density detections, and dark-grey squares correspond to $\geq 10\sigma$ over-density detections; the filled squares that are circled with a dark square correspond to cases where the CMD provides significant support to the detection. Light open circles are dwarf galaxies in the Local Volume in the considered range of M_V , from the catalog by McConnachie (2012). The three panels correspond to compact (upper panel), average (middle panel), and diffuse (lower panel) galaxy models.

ies, also systems as faint as $M_V = -5.0$ can be detected out to $D=1.0$ Mpc. In all the panels of this figure we over-plotted the distribution of dwarf galaxies in the Local Volume in the considered range of M_V , from the catalog by McConnachie (2012), for reference. We note that, in the considered case, any known dwarf with $M_V \leq -6.0$ would have been detected in SECCO. Moreover, the sensitivity of our survey extends to much larger distances than those spanned by known dwarfs in the range $-7.0 \leq M_V \leq -9.0$ (see Sect. 6 for further discussion on this point).

In worst-quality data (Fig. 9) we will still be able to detect any dwarf with $R_h \leq \bar{R}_h(M_V)$ out to $D = 2.0$ Mpc for $M_V = -9.0$ and out to $D = 1.5$ Mpc for $M_V = -8.0$. Compact dwarfs are seen out to $D = 1.0$ Mpc also for $M_V = -7$, while only the brightest and most nearby *diffuse* galaxies can be detected. We will show below that for $M_V \leq -10.0$ even diffuse galaxies would have been detected by visual inspection in SECCO images, independently of the considered dataset.

It is worth noting that in the majority of the considered cases the nature of the detected (or undetected) over-density can be ascertained from the inspection of its CMD. Finally we note that, within the considered grid of models, the lowest central surface brightness corresponding to a $\geq 5\sigma$ over-density is $\mu_{V,h} = 30.0$ mag/arcsec².

Fig. 9. Summary of the density map sensitivity experiments for *Worst case* SECCO observations. The meaning of the symbols is the same as in Fig. 8.

4. Sensitivity of the visual inspections

In this section we provide a basic exploration of the process of search of stellar counterparts by visual inspection of the images. This is mainly intended (a) to assess the luminosity limit above which a typical dwarf cannot be missed on our image, (b) to provide general guidelines on what we can expect to detect in our images, and (c) to provide a framework to interpret actual detections, obtaining rough constraints on the characteristic of a detected system by comparison with images of synthetic galaxies.

In Fig. 10 we show few examples of portions of *Worst case* images centred on a synthetic dwarf galaxy that was added as described in Sect. 2.2. We show these images here as reference to help the reader to have a feeling of the quality to the adopted datasets and of the realism of the simulations. A set of figures analogous to Fig. 10 are presented in Appendix B for the most relevant knots of the grid of considered models (Table 1).

The first three panels of Fig. 10 (from left to right and from top to bottom), show images of a synthetic dwarf galaxy with $M_V = -10.0$ and $R_h = \bar{R}_h(M_V)$ located at the distances of 1, 2 and 5 Mpc, respectively. The fourth (lower right corner) shows the original “empty” image, for reference. A circle of radius equal to the half-light radius is over-plotted, for reference, and its value in arcsec is also reported.

In the case of the visual inspection, the examination of the stacked images including synthetic dwarfs allowed us to draw the following conclusions:

- $M_V \leq -10.0$ dwarfs out to $D= 5$ Mpc would have been detected in SECCO by visual inspection, independently of the quality of the available observational material and of the galaxy size, within $R_h = \bar{R}_h(M_V) \pm 1\sigma_{\log R_h}$. As unassuming as it may appear (Fig. B.1), even the diffuse models are clearly noticed when the images are carefully inspected as we did for real SECCO images (Pap I; see Sect. 5, for real exam-

Fig. 10. Synthetic dwarf galaxies of $M_V = -10.0$ added to SECCO *Worst case* images, for different assumptions of the distance. All the stamp images are centred on the center of the synthetic galaxy; a circle with radius $=R_h$ is over-plotted. The stamp image in the lower right corner is the original image, without synthetic galaxy, that is shown for reference with a conventional circle of radius $= 30''$.

ples). These very low surface brightness galaxies are pretty evident when a simple gaussian smoothing of a few pixels is applied to the images.

- the effect of galaxy size is even stronger in images than in density maps. In fact, it turns out that no diffuse model is detected by visual inspection for $M_V \geq -9.0$; in the following of this section we will not deal anymore with diffuse models.
- in our survey, galaxies can be partially resolved up to $D \simeq 3.0$ Mpc. As unresolved systems they can be detected out to relatively large distances (see, again, Sect. 5).

The results of the critical analysis of the entire set of images with synthetic galaxies is summarised in Fig. 11. It is clear that visual inspection is a useful complement to the density map analysis but does not significantly enhance the sensitivity of the survey in the range of distances that is of primary interest for SECCO, i.e. $0.25 \text{ Mpc} \leq D \leq 2.0 \text{ Mpc}$ (see Pap I).

On the other hand it extends the sensitivity of the survey to larger distances, especially for compact models. Once again, the example of SECCO 1 (at $D \simeq 16.5$ Mpc) is fairly illustrative: the curious configuration of a few blue stars triggered the attention during the visual inspection of the images but was largely below the detection threshold in density maps (Pap I). In Sect. 5, below, we empirically demonstrate our ability to spot unassuming spheroidal dwarfs as faint as $M_V \sim -8.0$ at the distance of the Virgo cluster, independently of their position in the field.

The synthetic galaxy with the lowest surface brightness that we detect by visual inspection has $\mu_{V,h} = 28.1 \text{ mag/arcsec}^2$, almost two magnitude brighter than the limit achieved with density maps. This can be taken as the fundamental sensitivity limit for visual inspection of SECCO images⁸.

⁸ With a simple rescaling on aperture photometry we obtained rough estimates of the magnitude and surface brightness of the faintest among

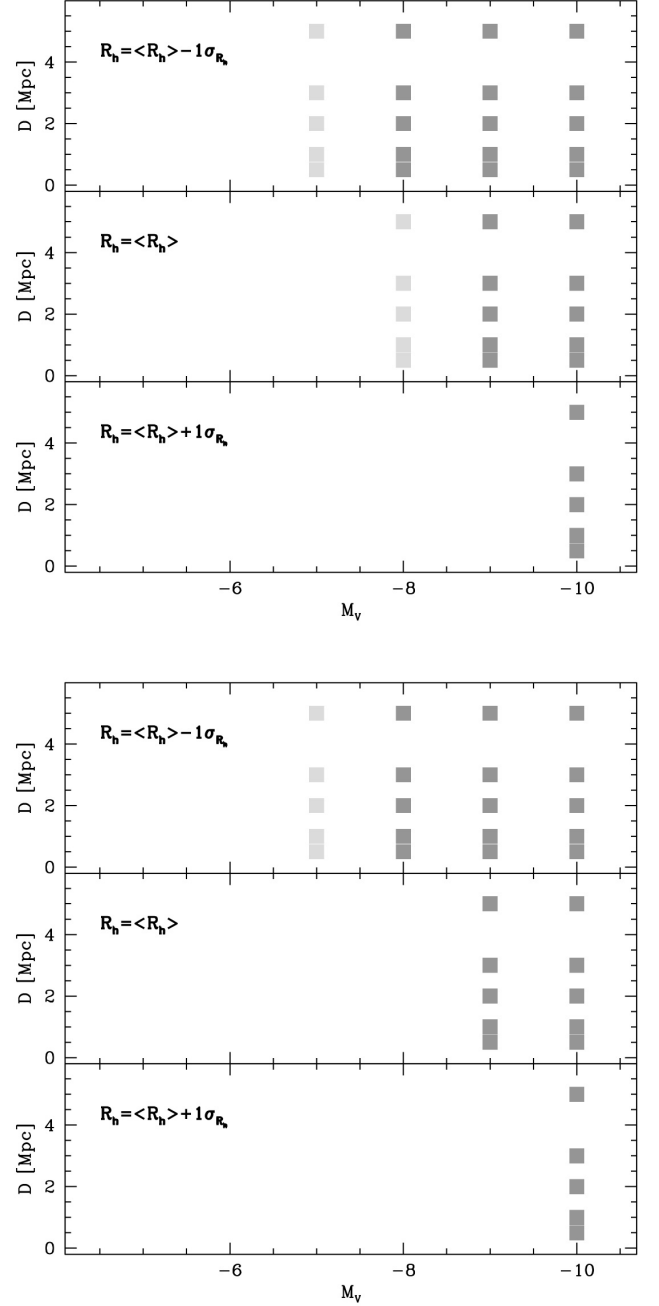

Fig. 11. Summary of the visual inspection sensitivity experiments for *Best case* (upper panels) and *Worst case* images. Dark and light grey squares indicate a clear and doubtful detection, respectively.

We are aware that the simple approach adopted for this part of the analysis may suffer from significant bias in favour of detection, especially for faint dwarfs ($M_V < -9.0$). A bias may be caused, for example, by placing the synthetic galaxy near the center of the field and by avoiding the superposition with heavily saturated stars (see Sect. 2.2). To fully reproduce the actual process of visual inspection performed on real data we should have

the Virgo dwarf spheroidal presented in Sect. 5, VC1 and VC2. We find $M_V \sim -7.0$ and $\mu_{V,H} \sim 27.8 \text{ mag/arcsec}^2$ (VC1), fully consistent with the limits from synthetic dwarfs.

produced a large number of images in which synthetic galaxies are added at random position within the field and/or not added at all; then we should have these images independently inspected by two of us, as done in Pap I. However, such an expensive approach would not add any significant piece of information with respect to the main goal of the overall analysis, since, as said, density maps have a much higher sensitivity than visual inspection in the crucial region of the parameter space. On the other hand the basic procedure described in this section is adequate to get a quantitative idea of the visibility of dwarfs at larger distances than those sampled by the density maps. Finally, in Fig. 11 we distinguish between cases in which the galaxy cannot be missed and less obvious detections, thus providing additional guidance on this aspect.

5. An empirical test: Low Surface Brightness dwarfs in Virgo

During the visual inspection of SECCO images (Pap I) we identified seven fluffy and roundish unresolved Low Surface Brightness (LSB) galaxies with typical diameters of $20'' - 40''$. Six of them lie in three of the four (over 25) SECCO fields that are projected within the wide boundaries of the Virgo cluster of galaxies (Kim et al. 2014). The Virgo cluster is known to host a large population of faint LSB galaxies that can be classified as dwarf spheroidals (dSphs, see, e.g., Phillips et al. 1998; Sabatini et al. 2003; Caldwell 2006, and references therein). It is likely that a large fraction of this population is still to be discovered; the ongoing Next Generation Virgo Survey (NGVS, Ferrarese et al. 2012) is expected to provide a fundamental contribution in this respect (see, e.g. Davies, Davies & Keenan 2015; Mihos et al. 2015). Hence it is reasonable to assume that the LSB galaxies we discovered in SECCO are physically associated to the Virgo cluster.

We decide to briefly report on them here for two main reasons. First they are interesting on their own, since they appear among the faintest and lowest surface brightness dwarfs ever discovered in Virgo, also showing intriguing clustering properties and, second and most relevant for the present paper, they provide real examples of how faint LSB dwarfs have been *actually found* by visual inspection in SECCO, thus giving independent support to our sensitivity analysis based on synthetic galaxies. Finally, three of them have been found in the same images where SECCO 1 (also likely lying in Virgo) has been found (Field D, see Pap I and Bellazzini et al. 2015b) thus providing the basis for a fruitful comparison with that stellar system, that appears peculiar under various aspects. The seven LSB systems are listed in Table 2, where the adopted naming convention is also defined. In the following we will drop the “SECCO-LSB” suffix for brevity. None of the listed systems is found in the Simbad⁹ or NED¹⁰ astronomical databases, nor in the recent catalogs by Kim et al. (2014) and Davies, Davies & Keenan (2015, with one exception, see Tab. 2)¹¹.

Fig. 12 displays the three LSB dwarfs found in Field D in a single zoomed image. This is possible because they are remarkably close together. Of the six candidate dSphs that we find in the 2131 arcmin^2 covered by the four SECCO fields sampling Virgo,

Fig. 12. A portion of Field D g-band (upper panel) and r-band (lower panel) images enclosing the three LSB galaxies identified in this field. North is up, East to the left.

(these) three lie within a circle of area $\approx 11 \text{ arcmin}^2$, hardly consistent with a random distribution, thus suggesting a physical association (see below for the case of VC1 and VC2). At the distance of 16.5 Mpc (adopted as the mean distance to Virgo, Mei et al. 2007), the projected separation between the centres of VD1 and VD2 is 4.8 kpc, a distance comparable with the sum of their apparent diameters; VD3 is just 17.5 kpc from VD1. While inspecting NGVS images we noted another similar LSB dwarf lying just beyond the northern limit of the SECCO image of Field D, at $\approx 5.2' \approx 25.0 \text{ kpc}$ from VD1, in the approximate position (RA, Dec)=(185.310 deg, 13.675 deg)).

We used GALFIT (Peng et al. 2010) to estimate magnitudes, radii and central surface brightness of the LSB dwarfs lying in Field D. We limit this analysis to VD1, VD2 and VD3 because they are the most prominent dwarfs of the sample and to have quantitative benchmarks to compare with SECCO 1, from exactly the same images. We fitted Sersic models to the g and r images. At a first pass we leave also the Sersic index n_s as a free parameter, then we repeated the fit keeping n_s fixed at the best-fit value of the first pass. All the three galaxies have $n_s \leq 1.0$, as typical of faint dwarfs in Virgo (Côté et al. 2007). Their integrated magnitudes, half-light radii and central surface brightness, as derived with GALFIT, are listed in Table 2. We remark here that we made no attempt to mask background sources, hence the reported photometry may suffer from some contamination (in particular VD1 that overlaps with a compact group of galaxies in the background, SDSSCGB22677, McConnachie et al. 2009). Moreover VD1 and VD2 lie near a corner of Field D and are partially out of one of the two g+r pairs of SECCO images of Field D, and the adjacent bright star provide a higher than average and spatially variable background. Hence the obtained surface photometry is not optimal. From the comparison of the independent measures on two images per passband for VD3, keeping a conservative attitude, we conclude that the typical uncertainty on integrated magnitudes and central SB are $\lesssim \pm 0.3 \text{ mag}$ and $\lesssim 20\%$ on R_h . When $D=16.5 \text{ Mpc}$ is assumed, VD1, VD2 and VD3 have $M_V = -12.4, -10.9$, and -8.2 , respec-

SECCO-LSB-U1 ^c	167.39125	+5.31381					21.3
SECCO-LSB-VX1	188.48816	+8.40119					4.1

Notes. The last group of letters in the ID (after SECCO-LSB-, whose meaning is obvious) may contain a V, indicating the likely association with Virgo, and then the letter of the SECCO field where the galaxy has been found (in this case Field C, Field D and Field X; see Pap I), and finally a number to distinguish between dwarfs lying in the same SECCO Field. D_{M87} is the angular distance from the M 87 galaxy, here taken as a proxy for the center of the Virgo cluster.

Integrated magnitudes and surface brightness values have been corrected for reddening assuming $E(B-V)=0.048$ (Pap I).

^a Particularly uncertain because of the faintness of the object.

^b Same coordinates, within 1.0'', of LSBVCC357 listed by Davies, Davies & Keenan (2015). ^c This galaxy lies ~ 4° beyond the zero velocity boundary of Virgo as estimated by Karachentsev & Nosonova (2010), between the Leo I and Leo II galaxy groups, both lying at a distance of about 10-12 Mpc from us, according to the NED database.

tively, and they fit nicely into the M_V vs. R_h and M_V vs. $\mu_{V,0}$ relations defined by local dwarfs (McConnachie 2012).

The g and r band images of the remaining LSB dwarfs listed in Tab. 2 are shown in Fig. 13. It is worth noting that, similarly to the case of Field D, also the two objects identified in Field C are very close one another. VC1 and VC2 are separated by just 1.0' in the plane of the sky, corresponding to ≈ 4.8 kpc at the distance of Virgo. Our sample of Virgo LSB is indeed too scanty to draw any general conclusion, but it is quite intriguing to note that five of the six galaxies more certainly attributable to Virgo are seen in very tight groups of two and three dwarfs.

The LSB dwarf found in Field U is ~ 4° beyond the zero-velocity contour of the Virgo cluster derived by Karachentsev & Nosonova (2010, ~ 17°), hence it cannot be considered as a member of Virgo. However it is located, in the plane of the sky, in the middle between two galaxy groups (Leo I and Leo II/NGC 3607) that lie at similar distance; if it is associated with such groups, as it seems likely, also U1 is a dwarf galaxy similar to the other ones listed in Table 2.

The detection of the faint LSB dwarfs discussed in this section fully support the results presented above, providing an independent empirical validation of the search by visual inspection we performed in Pap I and of the quantitative sensitivity analysis presented here.

5.1. Comparison with SECCO 1

Figure 14 allows a direct comparison of the size, brightness, morphology and colours of SECCO 1 and of the LSB dwarfs identified in the same SECCO images (Field D). The (reasonable) assumption that all the considered stellar systems lie within the Virgo cluster makes the comparison especially insightful. On the left panel of the image we have highlighted the main body of SECCO 1 (Bellazzini et al. 2015b) as well as the possible secondary body identified by Sand et al. (2015). Here we have highlighted with an ellipse a possible additional grouping of blue stars that may be associated with the system; a similar swarm of faint blue stars is also seen just to the east of the secondary body. If these structures are indeed physically associated, then SECCO 1 is a system even more complex and anomalous than already believed (Adams et al. 2015), and a tidal (Duc 2012) or ram-pressure (Fumagalli et al. 2011; Yoshida et al. 2012) strip-

ping phenomenon would gain support as an hypothesis for its origin (see Bellazzini et al. 2015b).

The comparison with the Virgo dSphs lying in the same image, in particular with the faintest and most diffuse one, VD2, lead to some interesting conclusions:

- any diffuse component associated to SECCO 1 should be *significantly fainter* than the central SB of VD2, i.e. $\mu_V \ll 26.5$ mag arcsec². The comparison with our simulated images consistently indicates that it should be in fact $\mu_V \ll 27.0$ mag arcsec²
- any diffuse component associated to SECCO 1 is *significantly bluer* than the dSphs. Indeed some very feeble fuzzy blue light is seen within the circle enclosing the main body, especially to the east of the brightest sources, and in the middle of the secondary body.

6. Summary and conclusions

We have complemented the search for stellar counterparts in 25 selected ALFALFA UCHVCs (A13), performed in Pap I, with a wide set of experiments with synthetic dwarf galaxies, in order to quantitatively assess the sensitivity of the SECCO survey. We have explored a grid of models of old and metal-poor stellar systems in the range $-5.0 \leq M_V \leq -10.0$. The stars of the synthetic dwarfs are distributed according to an exponential profile with three different R_h values spanning the $\pm 1\sigma_{\log R_h}$ range about the mean M_V vs. R_h relation as modelled by Brasseur et al. (2011, based on local galaxies). We analysed the sensitivity of stellar density maps in the range $0.25 \text{ Mpc} \leq D \leq 2.5 \text{ Mpc}$, and the sensitivity of visual inspection of the images in the range $0.25 \text{ Mpc} \leq D \leq 5.0 \text{ Mpc}$.

We fully confirm and extend the results of Pap I. In particular, we can now safely conclude that:

1. There is no dwarf galaxy with $R_h \leq \bar{R}_h(M_V) + 1\sigma_{\log R_h}$ and $M_V \leq -10.0$, within $D \leq 5.0 \text{ Mpc}$, associated to any of the 25 A13 UCHVCs studied by SECCO.
2. There is no dwarf galaxy with $R_h \leq \bar{R}_h(M_V) + 1\sigma_{\log R_h}$ and $M_V \leq -9.0$ within $D \leq 1.0 \text{ Mpc}$ associated to any of the 25 A13 UCHVCs studied by SECCO.

Fig. 14. RGB color stacked images of SECCO Field D centred on SECCO 1 (left panel) and VD1, VD2 and VD3 (right panel). The images have been obtained using the r-band image for the R channel and the g-band image for the G and B channels. The most remarkable structures have been labelled and enclosed with circles/ellipses whose size is reported.

Fig. 13. g-band (left panels) and r-band (right panels) stamp images of the LSB galaxies found in Field C (upper pair of images), Field X (middle pair of panels), and Field U (lower pair of panels). North is up, East to the left.

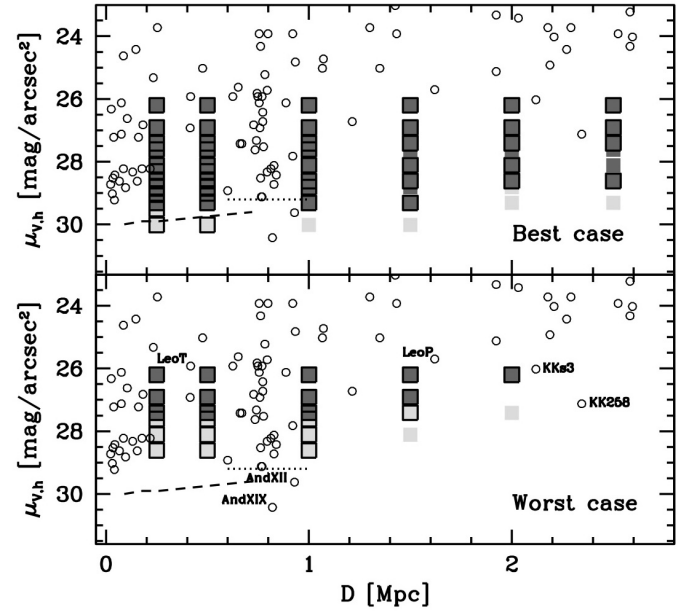

Fig. 15. Sensitivity of density maps for *Best* (upper panel) and *Worst* (lower panel) cases in the Distance vs. surface brightness plane. The symbols are the same as in Fig. 8. In particular, light open circles are known dwarf galaxies in the Local Volume, from McConnachie (2012). Central surface brightness values reported in the McConnachie (2012) catalog have been transformed into $\mu_{v,h}$ assuming exponential profiles, an acceptable approximation in the considered range of luminosity (Mateo 1998). We have labeled six remarkable systems. The dashed line is the SDSS detection limit as a function of distance for resolved stellar systems from Koposov et al. (2008, their Tab. 3); the dotted line is the detection limit of the PAndAS survey (Ibata et al. 2007) in the surroundings of M31, from Brasseur et al. (2011).

3. If we consider only dwarfs having $R_h \leq \bar{R}_h(M_V)$, there is no galaxy with $M_V \leq -9.0$ within $D \leq 2.0$ Mpc (as well as no

galaxy with $M_V \leq -8.0$ within $D \leq 1.5$ Mpc) associated to any of the 25 A13 UCHVCs studied by SECCO.

4. If we consider the 9 SECCO Fields with the best data quality (namely, A, G, B, Y, R, K, U, C, L; see Pap I) we can conclude that there is no dwarf with $M_V \leq -8.0$ within $D \leq 2.5$ Mpc (as well as no galaxy with $M_V \leq -7.0$ within $D \leq 1.5$ Mpc) associated to the corresponding A13 UCHVCs.

Thus we fully confirm the lack of $M_V \leq -8.0$ local counterparts to ALFALFA UCHVCs already mentioned in Pap I and, later, confirmed on the whole A13 sample but with shallower and less homogeneous data by (Sand et al. 2015).

In Fig. 15 we provide a complementary view of the summary of our results presented in Figures 8 and 9, above, that may help to express our sensitivity limits in a more synthetic form, in the Distance vs. Surface Brightness plane. In *Best case* observations, we can detect as $\geq 5\sigma$ over-densities dwarfs with $\mu_{V,h} \leq 30.0$ mag/arcsec² out to $D \leq 1.5$ Mpc, and those with $\mu_{V,h} \leq 29.5$ mag/arcsec² out to $D \leq 2.5$ Mpc. In *Worst case* observations, we can detect as $\geq 5\sigma$ over-densities dwarfs with $\mu_{V,h} \leq 28.8$ mag/arcsec² out to $D \leq 1.0$ Mpc, and those with $\mu_{V,h} \leq 27.6$ mag/arcsec² out to $D \leq 2.5$ Mpc. More specifically, the comparison with the distribution of known dwarfs in the Local Volume (from McConnachie 2012) shows that, for all the surveyed fields, independently of the quality of the available data:

- we would have detected any galaxy lying in range of distances and surface brightness inhabited by known LV dwarfs (except perhaps And XII, And XIX, KKs3, and KK258, with Worst case observations)
- our sensitivity region extends into a range of low surface brightness and large distances (for $1.0 \text{ Mpc} \leq D \leq 2.5 \text{ Mpc}$) that appears as largely unexplored, at present.

In particular, Fig. 15 shows that our survey is sensitive to dwarfs much fainter than the prototypical gas-rich faint dwarfs Leo T and Leo P.

It is important to stress here that $M_V = -10.0$ corresponds to $8.5 \times 10^5 L_{V,\odot}$, $M_V = -9.0$ to $3.4 \times 10^5 L_{V,\odot}$, $M_V = -8.0$ to $1.3 \times 10^5 L_{V,\odot}$, and $M_V = -7.0$ to $5 \times 10^4 L_{V,\odot}$. Since star-forming galaxies have stellar mass-to-light ratios $M/L \leq 1.0$, these translates into quite strong constraints in terms of total stellar mass of any stellar counterpart that went undetected in SECCO. For example, assuming a distance of 1.0 Mpc A13 concluded that ALFALFA UCHVCs span a range of H I masses $10^5 M_\odot \lesssim M_{\text{H I}} \lesssim 10^6 M_\odot$. This would imply that any associated stellar system not detected in SECCO would typically have $M_{\text{H I}}/M_* \gtrsim 10$, a value significantly higher than what found in normal star-forming dwarfs (see, e.g. Cannon et al. 2015; Bellazzini et al. 2015b; Sand et al. 2015) but quite typical of extremely metal-poor galaxies (XMPs, Filho et al. 2013).

In conclusion, the results of our very deep and homogeneous survey concerning local counterparts of High Velocity Clouds is fully in line with the various unsuccessful attempts performed in the last two decades (see, e.g., Simon & Blitz 2002; Willman et al. 2002; Hopp, Schulte-Ladbeck & Kerp 2003, 2007; Siegel et al. 2005, and references therein). The novelty is that, on the other hand, some more distant counterpart begins to emerge (Pap I, Bellazzini et al. 2015b), especially among the GALFA-HI candidates (Sand et al. 2015). The follow up of these counterparts and further searches in better defined samples of candidates may provide crucial insight on the census and the evolution of very low mass star-forming dwarfs.

Appendix A: Sensitivity of density maps: a summary table

In Table A.1 we summarise the results of our experiments for the detection synthetic dwarf galaxies with density maps described in Sect. 3 and illustrated in Fig. 8 and Fig. 9, above.

Table A.1. Classification of the over-density detections

M_V	k^a	D	B_{10}	B_5	B_{CMD}	I_{10}	I_5	I_{CMD}
-9.0	-1	0.25	1	1	1	1	1	1

Notes. ^a indicates compact ($k = -1$), average ($k = 0$) or diffuse ($k = +1$) models, where $R_h = \bar{R}_h(M_V) + k\sigma_{\log R_h}$.

$B_{10}(I_{10}) = 1$ indicates a $\geq 10\sigma$ detection in Best(Worst) case observations (Field B and Field I, respectively).

$B_5(I_5) = 1$ indicates a $\geq 5\sigma$ and $< 10\sigma$ detection in Best(Worst) case observations (Field B and Field I, respectively).

$B_{CMD}(I_{CMD}) = 1$ indicates that the inspection of the CMD provide significant support to the classification of the detected over-density as a dwarf galaxy.

Appendix B: A small Atlas of synthetic dwarfs

tional condition (Field B: best conditions, Field I: worst conditions) we simulate the galaxy image for five different distances ($D=0.5, 1.0, 2.0, 3.0,$ and 5.0 Mpc). This is represented, in the following, with six-panels figures with the stamp images of the given model for the five considered distances and a sixth panel showing the original empty image. In each of the six panels, the characteristics of the model as well as the considered value of the distance are clearly reported. A circle with radius equal to R_h is superimposed and its value in arcsec is reported. Usually the images in the last four stamp-size panels have the same scale, while the first two are zoomed out to include the radius= R_h circle. The lower set of panels in Fig. B.1 shows that a $M_V = -10.0$ would have been visually detected in SECCO images even in fields with the worst image quality and for *diffuse* models, i.e. dwarfs with $R_h = \bar{R}_h(M_V) + 1\sigma_{\log R_h}$.

In this appendix we provide images of synthetic galaxies exploring the most relevant cases for establishing the sensitivity limits of our survey. We feel that this small atlas of synthetic dwarfs can be of general utility to interpret images of candidate dwarfs obtained with 8m class telescopes. For a given galaxy model (identified by its M_V and R_h values), and for a given observa-
